Abstract Molecular characterization of different genotypes reveals accurate information about the degree of genetic diversity that helps to develop a proper breeding program. In this study, a total of 30 EST-based simple sequence repeat (EST-SSR) markers derived from trumpet lily (*Lilium longiflorum*) were used across 11 native lily species for their genetic relationship. Among these 30 markers, 24 SSR markers that showed polymorphism were used for evaluation of diversity spectrum. The allelic number at per locus ranged from 1 at SSR2 locus to 34 alleles at SSR15 locus, with an average of 11.25 alleles across 24 loci observed. The polymorphic information content, PIC, values ranged from 0.0523 for SSR9 to 0.9919 for SSR2 in all 24 loci with an average of 0.3827. The allelic frequency at every locus ranged from 0.81% at SSR2 locus to 99.6% at SSR14 locus. The pairwise genetic dissimilarity coefficient revealed the highest genetic distance with a value of 81.7% was in between *L. dauricum* and *L. amabile*. A relatively closer genetic distance was found between *L. lancifolium* and *L. dauricum*, *L. maximowiczii* and *L. concolor*, *L. maximowiczii* and *L. distichum* (Jeju), *L. tsingtauense* and *L. callosum*, *L. cernuum* and *L. distichum* (Jeju ecotype), of which dissimilarity coefficient was 50.0%. The molecular fingerprinting based on microsatellite marker could serve boldly to recognize genetically distant accessions and to sort morphologically close as well as duplicate accessions.

Keywords EST-derived simple sequence repeats (EST-SSR),

Genetic diversity, Native lily, Polymorphic information content (PIC).

Introduction

The genus *Lilium* from family liliaceae is widely dispersed in temperate areas like Europe, Asia, and North America (Liang et al. 2000; Patterson et al. 2002). Lily is a main flowering crop next to rose worldwide, in the market of cut flower. They have medicinal, food and economic value. Lilies are perennials herb with an abundant number of species and cultivars growing in open field and propagate asexually form underground scaly bulbs (Simpson 2011). Hybrid varieties have been generated making cross between *Lilium* species using conventional breeding as well as selections technique based on morphological characteristics like flower colors and shapes (Van Tuyl et al. 1991). Most of genetic diversity studies in *Lilium* are mainly dependent on morphological traits, but attempts were made in the diversity test for disease resistance such as *Fusarium* or *Botrytis* (Jang et al. 2015; Jang et al. 2018).

The cytological and morphological studies have been replaced by molecular studies like inter-simple sequence repeat, internal transcribed spacer (ITS) regions of rRNA genes and randomly amplified polymorphic DNA. Molecular marker studies in *Lilium* are not advanced compared to other plant species because of their large genome sizes. Molecular studies of wild *Lilium* species has been increasing and the reported molecular markers are ISSR (Xi et al. 2012), SRAP (Robarts and Wolfe 2014), RAPD (Huang et al. 2009), and ITS (Kumari et al. 2018; Sultana et al. 2011) to explore diversity of wild *Lilium* species. So, molecular techniques are required to systematically study of wild *Lilium* species in depth. Molecular markers related to resistance traits can indirectly decreased breeding and selection processes by MAS (marker assisted selection)

especially in polygenic complex traits like lilies.

Genetic diversity analysis explains better variation degree between and within collected germplasm (Du et al. 2015; Biswas et al. 2018). Genetic diversity is a pre-condition for successful plant breeding (Du et al. 2015; Ulukan 2009). A lot of approaches have been applied in plant genetic diversity analysis which includes the use of morphological, biochemical, DNA-based markers and agronomical (Mohammadi and Prasanna 2003). But the selection of approaches are decided by objectives, required information and resources.

Out of various different molecular marker systems, satellite loci, also known like simple sequence repeat (SSR) has many benefits like high reproducibility, high polymorphism, high transferability and abundance over other systems (Biswas et al. 2018; Park et al. 2009). Molecular markers are potent tools to assess genetic variation and to elucidate genetic relationships among and within species. Simple sequence repeat (SSRs) is one of the most commonly used molecular markers. It is PCR-based marker that is not only sufficient across genome, but also cost-effective to be used. Compared with other markers, it is co-dominant, interspersed, abundant and highly reproducible all over the genome (Panaud et al. 1996; Temnykh et al. 2000).

The polymorphic SSR markers can be used efficiently to assist genetic grouping of lily genotypes and consequently lessen the timeline for development of lily cultivars. Therefore, the goal of this study was to establish the genetic relationship among native Korean lily genotypes that were collected in Korean peninsula, and ultimately select unique parents used for breeding program in Korea using SSR markers. This is the first study of its kind to report diversity analysis in the native Korean lilies using SSR markers, which will be greatly applicable when they are proved to be useful.

Materials and Methods

Plant materials

Eleven native lily species which were collected from different parts of Korea were used in this study. These include *Lilium distichum* Nakai (Martagon division; Malnari), *L. lancifolium* Thunb. (Asiatic division; Chamnari), *Lilium dauricum* Ker-Gawler (Asiatic division; Nalgae Haneulnari), *L. leitlinii* var. *maximowiczii* (Asiatic division; Joongnari), *L. tsingtauense* Gilg (Martagon division; Haneul Malnari), *L. callosum* Siebold & Zucc (Asiatic division; Tdangnari), *L. cernuum* Komar. (Asiatic division; Solnari), *L. concolor* Salisb. (Asiatic division; Haneulnari), *L. hansonii* Leichtl.

(Martagon division; Seom Malnari), *Lilium amabile* Palibin (Asiatic division; Teoljoongnari), and *L. distichum* Nakai (Martagon; Jeju Malnari). Native lilies and their floral characteristics have been reported previously (Kumari et al. 2018).

Isolation of genomic DNA

Lily bulbs of each species were planted and germinated plants were grown in a green house at $25^{\circ}\text{C} \pm 1^{\circ}\text{C}$ under natural conditions in a research farm of Chungnam National University. Genomic DNA was isolated from the leaves following CTAB method (Zheng et al. 1995). DNA samples are evaluated both qualitatively and quantitatively by Nanodrop Lite (Thermo Fisher Scientific Inc., U.S.A).

Selection of SSRs and amplification for genetic diversity evaluation

A total of thirty SSR primer pairs were chosen for genetic diversity analysis for eleven native lily species. Primers names, sequences and expected amplicon size were listed in Table 1. Primers indicating polymorphic bands were selected and those showing monomorphic banding patterns were not considered. Finally, twenty-four SSR markers were used for genotyping assays.

PCR amplification was performed in a cocktail of 20 μl containing template DNA 30 ng, 0.5 μM of forward and reverse primer each, Taq 2X Master Mix (New England Biolabs Inc. London, UK) and nuclease free water. The PCR reactions were conducted in TaKaRa PCR Thermocycler Dice (Takara Bio Inc., Japan) with initial denaturation step at 95°C for 5 min, 35 cycles of 95°C for 1 min, for 1 min at 50°C to 65°C and 72°C for 1min; and final extension at 72°C for 7 min.

The amplified SSR products were separated by 2.0% agarose gel electrophoresis. The DNA samples were electrophoresed using 0.5 X TBE buffer (pH 8.3) at 110 V for 20 ~ 40 min. on Mupid-2 Plus submarine electrophoresis system (Advance, Japan). The gel analysis was analyzed by GelAnalyzer (<http://www.gelalyzer.com/index.html>). Markers having polymorphic information content (PIC) values in the range of 0.0523 to 0.991 were selected.

Data analysis

Based on the presence or absence of bands, amplicons were scored for every SSR primer pairs, and a binary data matrix of 1 and 0 was generated for each marker system.

Microsatellite loci repeats were assayed based on the detected number of alleles observed with the PCR amplicon profile. Major allele frequency, PIC values were computed for each and every SSR locus using equation - $PIC = 1 - \sum p_i^2$, where p_i represents frequency of i^{th} allele (Shete et al. 2000). GenAlEx 6.5 was used to calculate diversity (Peakall and Smouse 2012). The binary data matrix was then analyzed by the NTSYSpc statistical package version 2.2 (Rohif 2002). The genetic similarity based on Jaccard's similarity coefficients was calculated using the matrix data. The relationships among eleven lily genotypes was displayed by two dendrograms constructed using the Unweighted Pair Group Method with Arithmetic Mean (UPGMA). The Pearson's correlation between similarity coefficients were determined from data among all eleven genotypes.

Results and Discussion

Allele spectrum for SSR polymorphism among native lily

All 30 SSR primer sets selected for amplification produced PCR amplicon and 6 primer sets produced monomorphic amplicons. Thus, a total of 24 primer sets producing high polymorphic bands were used to analyze the genetic relationship and diversity among eleven lily genotypes.

24 high polymorphic SSRs were selected for the genetic relationship analysis of 11 native lilies (Table 1). The clustering pattern exhibited that the native lilies formed distinct group in phylogenetic dendrogram. The degree of polymorphism among lily genotype was appraised by calculating the number of alleles and PIC values for every of the thirty SSR loci analyzed. A total of 342 alleles were observed at the loci of thirty microsatellite markers across eleven lily genotypes.

Table 2 List of 24 SSR markers with their allele frequency, number of alleles, diversity and PIC values found among 11 native lily genotypes

Mean		11.25	0.6505	0.3429	0.3827

The results showed that most of the primers produced distinct polymorphisms among the genotypes studied demonstrating the strong nature of microsatellites in informative polymorphism. Among the polymorphic markers, 2 produced two alleles each, 2 produced six alleles each, 3 generated seven alleles each, 2 produced 8 alleles each, 2 produces 13 alleles each, and only one produced 34 (maximum) along with other marker produced alleles varying from 10 to 31 (Table 3). The range of allelic number per locus is from 1 to 34 alleles with an average of 11.25 alleles across the 24 loci. The highest allelic number (34.0) detected in the locus SSR15 and the lowest alleles (1) were observed on SSR2.

The amplicon size in all 11 genotypes for each marker allele varied from 200–100 bp. produced by SSR6 and 3000–274 bp. produced by SSR15. Out of 342 alleles scored, all of 270 were established to be polymorphic. Maximum polymorphic allelic bands (34) were detected with the marker SSR15, while the minimum polymorphic allelic band (1) was obtained from SSR1.

Figure 1 represents an agarose gel image of amplified

fragments obtained by SSR15 & SSR16. A wide spectrum of produced 34 alleles was found with SSR15 locus, followed by 31 alleles in SSR16 locus. This demonstrates that these markers might be potentially employed for molecular characterization of native lilies from various sources. However, some markers produced only few alleles like SSR2 gave only one, SSR6 & SSR12 each gave only two. Three markers were robust enough to discriminate specifically various genotypes or incompatible accessions of the same genotype.

Evaluation of Genetic diversity based on PIC value

SSR markers are very high informative polymorphic like evident from its polymorphism information content PIC value. PIC value reflects allele diversity and frequency among varieties. The PIC value is a calculation of polymorphism among varieties for a marker locus applied in the analysis of linkage. The PIC value of every marker, which may be estimated based on its alleles, varied greatly for all evaluated SSR loci from 0.0523 to 0.9919 with an

average of 0.3827 (Table 3). The high PIC value 0.9919 was obtained for SSR2, followed by respectively SSR8 (0.8424), SSR11 (0.7975) and SSR20 (0.6274). The PIC values of 24 markers from 0.0523 to 0.9919 with an average of 0.3827 which are lower than *Lilium* genus (Lee et al. 2011), groundnut (Cuc et al. 2008), Cassava (Moyib et al. 2007), and maize (Enoki et al. 2002).

Species diversity based on genetic clustering using genetic distance indices

SSR genetic distance applies to the genetic variance among populations, which may be calculated by a variety of parameters in connection with frequency of a particular trait. By using the binary data that was obtained from sample DNA profile, UPGMA-based dendrogram was con-

Fig. 2 A UPGMA clustering dendrogram representing the genetic relationships among eleven native lilies on the alleles detected by twenty-four microsatellite markers

structed. Genotypes that are genetically derived from similar types are clustered together.

Using 63% similarity like the threshold for UPGMA clustering, we obtained four major genetic clusters (Fig. 2). Cluster I was the second biggest group containing four genotypes- *L. distichum*, *L. lancifolium*, *L. dauricum* and *L. cernuum*. This group contained two sub-clusters, a subgroup of *L. distichum* and *L. lancifolium*, and another subgroup of *L. dauricum* and *L. cernuum*. The subgroup of *L. distichum* and *L. lancifolium* showed 45.64% dissimilarity, whereas *L. dauricum* and *L. cernuum* in another group showed 54.01% dissimilarity Table 3.

Cluster II was the biggest group which contained four genotypes - *L. leichtlinii*, *L. hansonii*, *L. distichum* (Jeju), *L. tsingtauense* and *L. callosum*. Cluster II contained two sub cluster, one of *L. tsingtauense* & *L. distichum* (Jeju) which showed similarity 47.06%, second of *L. maximowiczii*, *L. hansonii* and *L. distichum* (Jeju). *L. hansonii* and *L. distichum* (Jeju) showed 45.64% dissimilarity. Cluster III and Cluster IV contained only lily genotype - *L. amabile* and *L. concolor* respectively.

Pairwise genetic dissimilarity

A dissimilarity matrix determines the relationship among various genotypes. The pairwise genetic dissimilarity indices (Table 3) suggested that the highest genetic dissimilarity was between *L. dauricum* & *L. amabile* with 81.65%; *L. dauricum* & *L. hansonii* with 76.38%; *L. dauricum* & *L. distichum* (Jeju) with 73.60%; *L. distichum* & *L. concolor*, *L. lancifolium* & *L. tsingtauense*, *L. lancifolium* & *L. hansonii*, *L. lancifolium* & *L. amabile*, *L. dauricum* & *L. tsingtauense*, *L. tsingtauense* & *L. amabile*, *L. cernuum* & *L. concolor* with 70.71%. The lowest genetic dissimilarity

was found among lilies was between *L. lancifolium* & *L. lancifolium*, *L. maximowiczii* & *L. tsingtauense*, *L. maximowiczii* & *L. callosum*, *L. maximowiczii* & *L. hansonii*, *L. hansonii* & *L. distichum* (Jeju) which showed 45.64%, followed by *L. lancifolium* & *L. dauricum*, *L. maximowiczii* & *L. concolor*, *L. maximowiczii* & *L. distichum* (Jeju), *L. tsingtauense* & *L. callosum*, *L. cernuum* & *L. distichum* (Jeju) which demonstrated average of 50.00%. In this way, SSR markers, which bear enough power of resolution, can be used to perceive the difference between genotypes. SSR markers are being used as a powerful tool to identify and to characterize genetically distant cultivars from various sources.

In conclusion, the study indicated that the lily SSR markers are robust molecular markers and are neutral, co-dominant and could be a potent tool to assess cultivars-genetic variability. The information about the genetic diversity will be very useful to properly identify and select appropriate parents for breeding programs. The other SSR or SNP markers produced from the transcriptome evaluation among lily populations in our group will be further evaluated for genetic map construction or exploring SSR or SNP loci which are inherited with traits of interest.
